MEMORANDUM FOR DISTRIBUTION

Subj: Center for Naval Analyses Research Contribution 382

CRC 382, "First-Term Survival and Encl: Reenlistment Chances for Navy Ratings and a Strategy for Their Use," by James Thomason, May 1979

Enclosure (1) is forwarded as a matter of possible interest.

This Research Contribution, prepared in connection with CNA's study of Manpower Personnel Policies in the All Volunteer Force, estimates CY 1973 male recruits' first-term survival (and reenlistment) chances in 37 Navy ratings. It then shows that the effects of specific recruit characteristics An assignment procedure to vary across ratings. exploit such variation could lead to an overall higher survival rate. Especially promising recruit characteristics for such a procedure include age, educational level, participation in the delayed entry program, and boot camp location. A similar pattern of variations is also shown with respect to reenlistment chances across ratings.

Research Contributions are distributed for their potential value in other studies and analyses. do not necessarily represent the opinion of the Department of the Navy.

INTRODUCTION AND SUMMARY

A Navy recruit generally has better chances of completing his first term of service in one rating than in another. Moreover, within the same rating, prior research shows that recruits' survival chances differ according to their specific pre-service characteristics (reference 1).

The work reported here assesses whether relations between survival chances and given recruit characteristics differ across ratings. The major finding is appreciable variation across 37 Navy A-school ratings, most notably with respect to age, educational level, participation in the delayed entry program, and boot camp location.

For example, whether a recruit was 17 rather than 18 years old at entry was irrelevant to his survival chances in more than two thirds of the ratings/groups. Education differences had no independent effects on survival rates in six of the 14 ratings/groups. Where lower educational levels did affect survival, the impact was virtually always strongly negative.

In nine ratings/groups, those whose entry to the service was delayed (DEP) had higher survival rates than non-DEPs, other characteristics held constant. The recruit's boot camp location (and experience) also affected his survival chances in nine ratings/groups. Boot camp in Orlando was always at least as favorable to survival as training elsewhere.

A recruit's race had independent effects on his survival chances in only two ratings/groups. Whether the new recruit had dependents affected his survival chances only in two ratings/groups. Lower mental group recruits (3L and 4) survived at lower rates in just one of the 37 ratings, other things equal. In two ratings/groups, lower mental group recruits actually had higher survival rates than did other men.

Where activity or tour-type assignments affected survival, duty on an amphibious ship, an auxiliary patrol vessel, a surface combatant, or with a sea-based air squadron always had an adverse effect relative to the modal assignment, whereas assignment to a

¹ The data set consists of semi-annual Enlisted Master Records for recruits who joined the regular Navy in CY 1973 and were assigned to Class A school. We aggregated ratings into 14 ratings/groups. Of these 14, four consist of single ratings (BTs, MMs, HTs, and ENs). The other 10 are groups of two or more similar ratings (see table 1). Groups were formed from ratings too small for separate treatment.

submarine or toured-sea duty always had a favorable impact. Only duty on a carrier had either a favorable or an adverse effect depending on the rating/group.

These new results have especially important implications for Navy assignment policies. A formal procedure, using network analysis or linear programming, could exploit such differences to increase first-term survival. Two general rules would govern all job assignments: 1) assign a recruit to the job that maximizes his expected survival chances; 2) if only one of two recruits can be placed in a given job using rule 1, assign the one whose expected survival chances are hurt most in another job.

Refinements could then incorporate various real-world complications, for example:

- recruits will not be equally qualified for every job;
- maximizing overall first-term survival may conflict with other goals, such as maximizing reenlistment or survival in specific jobs;
- recruit loss shortly after training may cost more than loss later in the first term;
- assignments must be made at least monthly, not just annually.

This report also presents estimated reenlistment rates for CY 1973 recruits who survived their first (four-year) term and then explores two major applications: as an aid in the search for reenlistees and as a component of a first-term job assignment procedure. Results indicate remarkably little conflict between assignment strategies for optimizing survival versus those for optimizing reenlistment. Of all logically possible conflicts between the best recruit characteristics for survival and those most favorable for reenlistment, only about five percent display such conflict.

Without applying a formal optimizing procedure we cannot know whether the Navy has already (albeit informally) fully used this opportunity to increase overall survival and reenlistment rates. Inspection of 1973 cohort rating/group means on selected recruit characteristics does suggest room for improvement.

SURVIVAL RATES AND OCCUPATIONAL ASSIGNMENTS

Prior CNA work (reference 1) examined CY 1973 recruits in two large ratings, boiler technicians and machinists mates, and specifically estimated their four-year survival chances as a function of pre-service and early in-service characteristics (see appendix A). The statistical technique used in that prototype analysis was a simple probit model estimated by maximum likelihood procedures (see appendix B). The work reported here extends that assessment to 35 additional ratings clustered into 12 more ratings or rating groups. All together, these 14 ratings/groups comprise most of the ratings requiring Class A school training.

Not all survival rate patterns (across ratings/groups) can be exploited to increase overall survival. For perspective on this, figure 1 presents a simplified set of possible relations between job (rating) assignments and survival chances. Assuming that the Navy enlists only two types of men and has only two types of jobs to fill, figure 1 indicates two scenarios of interest.

Two Structures

Figure 1's two scenarios differ in one crucial respect: type I affords the Navy no opportunity to increase overall survival rates by reassignment, whereas type II does.

Structurally the two scenarios differ according to whether the (signed) differences between cells in each row are equal (type I) or not (type II). This distinction is vital and is specified formally in the figure.

In type I scenarios there is no difference between row differences. Thus, even if one type of recruit is moved from one job to another to improve his survival chances, when one of the other type of recruit is (necessarily) transferred in the reverse direction there can be no net gain in overall survival, no matter how the two recruit types were distributed between jobs before the reassignment effort began.

The context of figure 1's scenarios is further simplified here by the following additional assumptions:

the Navy is concerned only with maximizing overall retention rates,

any recruit can do any job equally well, the attrition costs of all recruits are the same,

the attrition costs of recruits from any one job are the same as from any other job,

a fixed number of recruits is needed in a given job,

a fixed number of each recruit-type is available.

 $R_1 J_1 - R_1 J_2 = R_2 J_1 - R_2 J_2$ Condition (0) (a) (a) R

 $R_1J_1-R_1J_2 \neq R_2J_1-R_2J_2$ (c) J_1 (a) 50% (a) J_1 R₁ II

Only type II scenarios are exploitable:

Type IIa: Maximize R_1 's in J_1 , maximize R_2 's in J_2 Type IIb: Maximize R_2 's in J_2 . Type IIc: Maximize R_2 's in J_1 .

A fixed number of recruits is needed in each job type, and a fixed number of each recruit type is available. R_1 and R_2 represent two different recruit types; J_1 and J_2 represent two different job types. NOTE:

By contrast, in any type II situation there always will be (in principle) transfers from which the gain in survival rate will be greater than the loss (if any) due to the "reverse" transfer of the other recruit type. Consider situation IIc in figure 1. The R_1 row difference is (+.10) while the R_2 row difference is (+.15). A net gain (+.05) can therefore be achieved by moving even one R_2 to J_1 (unless all R_2 's were already in J_1), despite the "loss" thereby incurred because an R_1 must be moved from J_1 to J_2 . In brief, a net gain will always be possible where a type II scenario exists.

Three Issues

Given the logic sketched above, three major questions arise in considering the applicability of a formal occupational assignment procedure:

- 1. Do exploitable circumstances (scenario II) occur frequently?
- 2. Does the Navy already fully exploit such circumstances where they do exist?
- 3. Do complications to the scenarios such as unequal competence of different recruit types, higher costs attached to the loss (from service) of one type of recruit versus another, or unequal availability of particular recruit types make development of such a procedure either unworkable or trivial?

The work in this report addresses only the first question. Unless exploitable circumstances occur fairly often, there will be little merit in developing the formal assignment procedures needed to determine whether the Navy fully took advantage of scenario II conditions in assigning the 1973 cohort.

The third question cannot be answered without running at least an initial version of a formal procedure. The complications mentioned above are not intractable in principle. But if even preliminary results indicate that survival gains would have been small, the mere existence of such complications will mean that 1973 cohort members were assigned to jobs about as well as they could have been. In short, the first issue is the crucial one to resolve at this stage.

FOUR-YEAR SURVIVAL RATES

The Sample and Estimation Method

To decide how often exploitable job assignment conditions occurred, we first needed to estimate the four-year survival rates in each of the 14 Navy ratings/groups (see table 1) from pre-service and early in-service recruit characteristics (figure 2). The 1973 cohort was used for two reasons. Men enlisted during that year were the first to enter the all-volunteer force; furthermore, this cohort was the only AVF group to have completed four years of service as of December 1977.

Only men who survived at least the first six months of service are included in this sample, to permit occupational identification.

To estimate the effects of pre-service and service characteristics on survival rates, simple probit analyses were run on the four-year service records of sample recruits in each of the 14 ratings/groups shown in table 1.

Overall Average Survival Rates

Table 1 shows the average four-year survival rate of sample enlistees, the initial sample size, and the number of four-year survivors in each major rating/group. Although interesting differences appear across these ratings/groups, this information does not tell us how different types of recruits typically survive in each. Table 2 is designed to do that.

¹The estimation models also included recruit differences (within a given major rating/group) with respect to activity assignment, specific rating, and tour-type assignment (see figures 2 and 3).

²See appendix C for the proportions of each rating/group with given pre-service or in-service traits.

ano variation across recruits' ratings in these ratings/groups.

b"Other" means a residual-type (non-ship/squadron duty) activity assignment.

Effects of Pre-Service and Early In-Service Characteristics

Table 2 presents estimates of survival probabilities for various recruit types within each of the 14 ratings/groups. Important differences exist across groups in the estimated survival rates for the intercept (modal) recruit-type, i.e., one with all of the following pre-service and early in-service traits: Age (18); Race (Caucasian); Mental Group (1 or 2); Dependents (none); Education (12 years); DEP status (no delayed entry), RTC (Orlando). This type had an average survival rate which varied from a low of 56 percent (as a boiler technician or engineman) to a high of 83 percent (in the sensor systems group). Looked at in isolation, these results suggest that if the Navy wants to maximize survival rates among this type of recruit, it should give all of them sensor systems ratings. Clearly, however, that assignment strategy would create several problems.

However, table 2 also provides a means of approximating average survival rates for all other recruit-types, so we are not restricted to the intercept recruit in devising a job assignment

¹See appendix D for the detailed probit results for each major rating/group. Table 2 itself only presents probability changes for "non-intercept" characteristics which differ significantly (t > 1.64) from intercept characteristics in their effects on survival rates.

²Intercept estimates also apply only to recruits with four-year first-term obligations (at entry). Six ratings/groups had significant proportions of recruits with (entry) obligations other than four years: MMs, EM/ICs, ET/FTs, SENSORS, RM/CTs and Aviation Weapons. These six had appreciable numbers of six-year "obligors" at entry (6YOs). Virtually all 6YOs begin their service in specialized programs only available to highly qualified individuals. To compare four-year survival chances of the same recruit across ratings/groups, only recruits with four-year obligations (at entry) are discussed here. See appendix D for precise estimates of the (always favorable) impact on survival chances, other things equal, of being a 6YO at entry in these six ratings/groups.

strategy. 1 For example, to identify the survival rates (across major ratings/groups) of a recruit who is the intercept type except that he is 17 rather than 18 years old, we simply add the probability change(s) listed in the "17 year old" column of table 2 to the probability for the intercept type in that rating/group. Specifically, therefore, this "intercept except 17" type enlistee has his best survival chance in the sensor systems ratings (83 percent) and his worst chance as a machinists mate (57-6 = 51 percent). Suppose we also want to know the survival rates in various ratings/groups of a 17 year old non-Caucasian who went to boot camp at Great Lakes (RTC1) but in aise the intercept type. We would add the sum of the probability changes associated with each of those non-intercept traits to the intercept probability. For this type of recruit assigned to the health care group, for example, we would add -15(-4 + 5 - 16) to the intercept value of 78, for an average rate of 63 percent.

The results in table 2 can be summarized generally as follows. For some ratings/groups a particular pre-service or early in-service characteristic has significant (adverse or favorable) effects on survival rates, while in other ratings/groups it has none. For instance, whether a recruit was 17 years old at entry rather than 18 (the intercept value) is irrelevant to his survival chances in more than two thirds of the ratings/groups (10/14). In the other four, however, being 17 does make a difference.

Second, when a characteristic (such as being 17) does make a difference in terms of survival, the direction of the effect is overwhelmingly consistent. For example, for the ratings/groups in which it does make a difference, being 17 at entry has an adverse effect compared to the intercept value of 18 years. The following characteristics, when significant, have an adverse effect on survival (relative to the intercept term): age 17, presence of dependents, boot camp training at RTC1 (Great Lakes) or RTC2 (San Diego), and educational level less than 12 years (except for enginemen). On the other hand, when the following variables have an impact on survival (relative to the intercept term), it is

The procedure gives proper results when calculating survival chances of a recruit with one non-intercept characteristic, and yields approximately accurate probabilities even if the recruit has more than one non-intercept characteristic. In the latter case, however, the precise technique for calculating a recruit's survival chances is to add the probit coefficients for those characteristics to the intercept probit coefficient (see appendix D), find the corresponding probability from a cumulative standardized normal distribution table, and then subtract that probability from 100 percent. This yields a consistent survival probability estimate for that recruit type (see appendix B for an example).

favorable: age 19 and age 20 (or greater) at entry, mental groups 3L or 4, delayed entry (DEP), and education greater than 12 years.

Third, of the seven pre-service and early-in-service variables examined here, only boot camp location, delayed entry (DEP), and educational level have significant effects on survival rates in at least half the ratings/groups. On the other hand, inspection of table 2 will indicate that, among pre-service and early-in-service characteristics, the presence of dependents has the strongest average effect, (-.15) where it has any effect at all.

From the standpoint of improving overall first-term survival, however, the most important fact to emerge from table 2 is that the impact of a given characteristic on survival rates differs across ratings/groups. This means that, unless the Navy already fully exploits such patterns, an assignment procedure can be developed to improve overall survival rates.

Effects of Various Within-Rating/Group Assignments

Tables 1 and 2 refer to only 14 major ratings/groups. However, the survival rates estimated (in table 2) for different recruit types in each rating/group were based on a model that explicitly estimated (controlled for) any differences in survival rates attributable to recruit differences in Activity, Rating or Tour-type (ART). Each of the 14 ratings/groups in this sample has a modal ART profile, but that profile varies from one major rating/group to another (figure 3). Despite this variation, the modal ART profile for each rating/group was assigned to the intercept along with the modal pre-service and early in-service profile (no variation) in estimating survival rates for recruit types in that rating/group.

Table 3 summarizes our findings about the effects on survival rates of activity, rating, and tour-type assignment. Specifi-

The race variable and the mental group 3U characteristic each have significant effects on survival, other things equal, only in two ratings/groups: 1) the impact on survival of being non-Caucasian is adverse for aviation maintenance ratings, while for health care the impact is favorable; 2) the effect on survival of being in mental group 3U is favorable for aviation maintenance, but for boiler technicians it is negative.

²See appendix C for the proportion of each major rating/group assigned to a given activity, rating or tour-type.

braken from table 2 (above).

cally, the table indicates those ART types which, regardless of the recruit type we are discussing, affected survival chances (either favorably or adversely) in a way significantly different from any such ART types not listed (for the given rating/group) in table 3. Thus for BTs, assignment to a carrier (CV) was found to raise average survival chances by six (+6) "survival points" relative to the chances in any other activity. For MMs, assignment to a submarine (SUB) raised a recruit's average survival chances by 13 survival points relative to the chances of an MM assigned to any activity other than a SUB or an amphibious ship (AMPH). An MM assigned to an AMPH ship, however, had a survival chance nine survival points less (-9) than one assigned to a non-SUB activity. An MM assigned to an AMPH ship had an average survival chance 22 survival points lower (-22 = -9 -13) than did the same type of MM assigned to a submarine.

Table 3 also reflects the discovery that, for example, a BT assigned to a carrier on toured-sea duty had an average survival chance 12 survival points (6 + 6) greater than the same type of BT assigned neither to a carrier nor to toured sea duty, and an average survival rate six survival points (+6) greater than that of the same type of BT assigned either to a carrier or toured sea-duty (but not to both). $^{\rm I}$

The boiler technicians and the machinists mates are separate ratings. But rating groups include as many as five separate ratings (see table 1). For example, the sensor systems group covers three separate ratings (ET, OT, ST). Of these three, however, only the OT rating assignment significantly affected (-14) a recruit's survival chances when other (non-rating) characteristics were held constant. Another (equally legitimate) way to view this finding is to conclude that assignment to either of the two other ratings (ET, ST) enhanced a recruit's chances (+14) relative to an OT rating assignment, other things equal.

As was true for the pre-service and early-in-service characteristics, table 3 shows that a given activity or tour-type assignment has a significant effect on survival rates in some ratings/groups but not in others. Where these assignments do matter, the direction of the effect for a given assignment is also highly consistent across those ratings/groups. Where it affects survival, assignment to an amphibious ship, an auxiliary patrol vessel, a surface combatant, or to a sea-based air squadron always has an adverse effect relative to the modal assignment. Where it matters in terms of survival in a rating/group, assignment to a submarine or toured sea duty always has a favorable impact relative to the intercept assignment. Only assignment to a carrier has

 $^{^{1}\}mathrm{See}$ appendix B for the strictly proper calculation procedure.

either a favorable or an adverse effect on survival (where it has any significant effect at all) depending on the rating/group one is discussing. 1

¹One additional factor likely to affect survival and reenlistment rates in different ratings, other things equal, is the prospect of a reenlistment bonus, which varies by rating. Presumably, the larger the prospective bonus, the stronger the incentive both to qualify for reenlistment and then to reenlist, which at a minimum requires completing one's first term. However, discerning (any) specific effects of bonuses from this analysis is unlikely. Since the bonus was set up in large part to improve survival/reenlistment chances in ratings where they were especially low, and since we have no pre/post bonus-program information on survival and reenlistment rates, to infer the precise effects of such monetary incentives would be hazardous here.

OPTIMIZING SURVIVAL RATES THROUGH JOB ASSIGNMENT

Tables 2 and 3 together provide considerable information and allow us to make at least a first estimate of the prevale. • of exploitable situations among members of this cohort.

The profiles in table 2 reveal that such situations did exist. For example, the table indicates that the overall survival rate in the 1973 cohort could have been raised by:

- 1. assigning intercept recruits (instead of intercept
 -but-age 17 recruits) to each of the following
 ratings/groups: MMs, AVMs, DT/HMs, and LOGs, while at
 the same time;
- 2. assigning all intercept-but-17 year olds to any other ratings/groups.

A slight modification of this transfer rule could have improved overall survival even further. Instead of replacing intercept-but-17 logistics group ratings by the intercept type, the Navy could have replaced intercept-but-17 recruits by intercept-but-19 men. The intercept-but-19 recruits for that transfer could most easily have been drawn from (and intercept-but-17 men used to replace them in) any rating/group not exhibiting a negative probability change for the intercept-but-17 recruit.

More generally, overall survival improvements could have been achieved in principle had the Navy employed the following rules:

- assign recruits to ratings/groups where the cost (in "survival points") associated with their particular traits is minimized.
- 2. If only one of two recruits can be placed in a given rating/group using rule 1, assign the one whose expected survival chances are most adversely affected in another rating/group.

Table 2 indicates that quite a few such transfer possibilities could have been exploited in assigning this 1973 cohort. Furthermore, although the rules for exchanges among more fully non-intercept recruit types can rapidly become complicated, a large variety of advantageous transfers do seem to exist. Some of these complexities appear in the following example. Assigning intercept-but-17 type recruits who would have been MMs to be HTs instead (coupled with replacement of those 17 year old "MMs" by intercept type recruits who would have been HTs), could in principle have increased the overall 1973 cohort survival rate. But this increase would almost certainly not have resulted if the 17 year old "MMs" transferred to be HTs had attended boot camp in San Diego (RTC2).

The reasons for this constraint can be seen in table 2 itself: recruits from RTC2 had lower survival rates as HTs than as MMs, other things equal.

This kind of complexity to the interpretation of table 2 clearly suggests the value of a formalized assignment procedure, one which could generate and then quickly use more complex transfer rules to determine which set of "exchanges" would have been not only profitable but optimal vis-a-vis the overall survival rate.

REENLISTMENT RATES OF FOUR-YEAR SURVIVORS

Recruits who survive their first-term may or may not be declared eligible to reenlist. Even if eligible, however, they may not want to do so. In this section, the chances of reenlistment by recruits who entered the Navy in CY 1973 and survived their first, four-year term are estimated from the same set of pre-service and in-service characteristics used earlier to gauge their four-year survival chances. As in the prediction of survival probabilities, reenlistment chances are assessed for different four-year survivor types (defined by pre-service and in-service characteristics) within each of the 14 major occupational ratings/groups listed in table 4. Table 4 also provides information on the overall, average reenlistment rates of survivors from each of these 14 ratings/groups.1

Although instructive, the average reenlistment rates in table 4 do not take account of pre-service and in-service differences among survivors from each rating/group. Tables 5 and 6, by contrast, give us estimates of the reenlistment rates of different types of four-year survivors within each of the 14 ratings/groups.

Using an intercept profile for each rating/group identical to that employed above in estimating survival chances, table 5 first presents the average reenlistment rate for an intercept type survivor from each rating/group. Then it lists any significant (t > 1.64) change in probability of reenlistment attributable to the pre-service or early in-service characteristics included in the estimating model. Table 6 provides a comparable picture of any probability shifts associated with differences between survivors in their first-term activity assignments, ratings, and tour-types.

As with the survival estimates, tables 5 and 6 show that the effects of most given pre-service or in-service characteristics on reenlistment chances of survivors vary considerably from one rating/group to another. This is important for any strategy aimed at increasing reenlistment by occupational assignment. It means that there are occupational "reassignments" which could (in principle) increase the overall reenlistment rate of the cohort.²

¹All six-year obligors who survived four years were excluded from this analysis since they had not reached the reenlistment point.

 $^{^2}$ Whether the Navy can realistically permit the reassignments which would increase reenlistments is a separate and important issue.

aSurvivors listed in table 1 refer to those recruits who began service during CY 1973 and had completed at least four years of service by Dec. 1977. Table 4 survivors are defined to include only those (table 1) survivors who did not have six-year (first) terms of obligation, since true six-year obligors (6YOs) are not automatically at the reenlistment decision-point after four years.

braken from table 4 (above).

These tables also reveal that, for ratings/groups in which a given non-intercept characteristic does have a significantly different effect on the reenlistment chance of a survivor from the effect of its intercept counterpart, the direction (sign) of its effect is generally consistent across ratings/groups. Among the pre-service and early in-service characteristics assessed in table 5, only age 19 (with hull technicians), RTCl (with logistics ratings), and RTC2 (with sensor systems ratings and boiler technicians) exhibit signs contrary to this general pattern of directional consistency. I

Despite this consistency, most of the pre-service and early in-service characteristics exhibited little or no truly general relation (across ratings/groups) to reenlistment of four-year survivors. Age differences affected reenlistment only in five ratings/groups (HTs, AvWeps, DT/HMs, LOGs and ADMIN). RTC location made a difference only in six (BTs, MMs, SENSORs, DT/HMs, LOGs and ADMINs). Mental group distinctions were relevant to reenlistment only in six major ratings/groups (MMs, ENs, RM/CTs, AvMs, DT/HMs and LOGs). Education differences mattered only in four (ENs, SENSORs, AvMs, and ADMINs), and participation in the Delayed Entry Program (DEP) affected reenlistment chances only for SENSORs, AvMs, and ABASPR personnel.

On the other hand, both a survivor's race and whether or not he had dependents bore an important general relation to his probability of reenlistment. In ten of the 14 major ratings/groups, a non-Caucasian survivor was considerably more likely to reenlist than a Caucasian, other differences held constant. Similarly, in eight ratings/groups, survivors with dependents were appreciably more likely to reenlist than those without them, other factors held equal.

Interestingly, among activities, first-term submarine duty is always favorable to reenlistment, at least where it has an effect significantly different from the intercept, while first-term duty on a carrier is always unfavorable where it has a distinctive impact. Other activity assignments had varying effects depending on the rating/group considered. Table 6 also shows that, where tour-type did have an impact upon reenlistment chances, regular and toured sea duty were almost always more favorable than shore duty, and toured-sea was generally more favorable than regular sea duty.

¹Educational level (both "greater than 12 years" and less than 12 years) also shows different directions in its effect (relative to the intercept) depending on the rating/group examined, but EDGT12 and EDLT12 each have significant effects in only two ratings/groups.

None of the activity or tour-type assignments had a significant impact on reenlistment across more than half the ratings/groups. Assignment to a carrier (CV) did make a difference in four, and assignment to regular or toured-sea duty mattered in seven ratings/groups. But none of the other activity or tour categories had effects even that widespread on reenlistment.

APPLICATIONS OF REENLISTMENT ESTIMATES

The reenlistment probabilities presented in this paper can be used in at least two major ways. First, they could facilitate the search for reenlistees. Second, they could be used along with the survival results to develop a strategy for jointly maximizing first-term survival and reenlistment of survivors through a formal rating assignment procedure.

The Search for Reenlistees

Tables 5 and 6 can be used together to rank first-term survivors according to their reenlistment chances. Those survivor types with the highest expected reenlistment rates could be sought out first. The most general rank-ordering procedure would ignore survivors' first-term ratings in developing priorities among survivors; it would merely calculate which of all survivors are most likely to reenlist. For illustrative purposes, table 7 indicates the top ten types in such a general rank-order scheme.

On the other hand, such a scheme may be inadequate. The Navy may want to insure that it reenlists a reasonable number of men with prior experience in each of the major ratings/groups. In either event, the information in tables 5 and 6 can be adapted to the appropriate scheme.

Jointly Maximizing Survival and Reenlistment

A second application for these reenlistment estimates would be to develop a strategy for first-term rating, activity, and tour-type assignments that jointly optimizes first-term survival of recruits and reenlistment of first-term survivors. As noted above, to do this in comprehensive fashion will require a formal, programmed procedure. However, some initial insight into this strategy can be derived from the information in table 8, which displays those recruit characteristics most favorably affecting first-term survival and also reenlistment of four-year survivors, respectively, for each major rating/group.

Five basic patterns of relations between survival and reenlistment findings will be found in table 8. As an example of the first pattern, the table shows that boiler technicians who were 19 years or older (at entry) had a better survival chance than other age groups, other things equal, but that, among boiler technicians

 $^{^1}$ See appendix B for the precise calculation technique. The probabilities listed in table 7 are approximations only (based on tables 5 and 6).

deglar's more 'Adr': the variable did not have an independent effect, were home pairs indicate a conflicting pattern.

who survived four years, age differences had no independent effect on reenlistment chances. This is important. It indicates that the Navy could optimize the age profile of BTs for survival purposes without adversely affecting reenlistment chances of BTs who survive four years.

Exemplary of the second type of relation is that the racial profile of BTs has no independent effect on their survival rates, but that those who survive four years and who are non-Caucasian reenlist at considerably better rates, other things equal, than Caucasian BT survivors. This means that the Navy could in principle optimize the racial profile of BTs with respect to reenlistment without adversely affecting survival probabilities among first-term boiler technicians. The social acceptability of such a strategy is a separate issue.

Illustrative of the third pattern is the lack of effect of age differences on survival and reenlistment rates of enginemen (ENs), for example. No effects are evident. Consequently, the Navy could use any ratings/groups displaying this pattern as a "catch-all" location for any recruits who would be less favorably affected than other recruits by assignment to another rating/group.

A fourth relation emerges in table 8, for example, while examining the effect of mental group differences on survival and reenlistment among aviation maintenance ratings. First-term recruits in these ratings survive best if they are in MG 3 or 4, but four-year survivors from MG 3 lower or 4 reenlist most often, other things equal. In these ratings, therefore, there is only some congruence between mental groups most favorable for survival and reenlistment: AvM survivors in MG3U will reenlist less often than those in MG3L4, yet MG3U recruits will survive as often as those in MG3L4, other things equal. In such situations the Navy would do best (in jointly maximizing survival and reenlistment within the given rating/group) to assign only recruits at the intersection of the profiles most favorable for survival and reenlistment, e.g., MG3L4 (not 3U) to AvMs, other things equal.

The fifth and final pattern exhibited in table 8 can be seen, for instance, in the health care ratings (DT/HM) with respect to age differences. Here there is a direct conflict between the profile most favorable to survival (18 years or older at entry), and that most favorable to reenlistment (17 years at entry). In this type of situation more than in any other, a clear-cut decision must be made: what counts most, survival or reenlistment? If survival counts most, the appropriate strategy is to assign older recruits to health care ratings, other things equal. If reenlistment is the higher priority, 17 year olds should be preferred in those ratings.

Fortunately, this fifth (conflict) pattern occurs much less frequently than do the other four types just discussed, at least for the 1973 cohort. This means that, with careful planning, very few adverse effects on reenlistment rates will necessarily result from efforts to increase first-term survival rates through a formal occupational rating assignment procedure. More generally, the relative infrequency of this conflict pattern indicates that a strategy for increasing both survival and reenlistment rates by occupational assignment will confront no major obstacles wherein maximizing one value (higher survival rates) leads to reduced attainments on a second value (higher reenlistment chances).

From a practical standpoint, the reenlistment rates (of survivors) presented above will be far less useful by themselves than would be reenlistment rates at time of entry for given types of recruits (each given by a particular pre-service/early in-service profile), depending on which rating/group they might be assigned to. Only the latter estimates can be used directly in a first-term assignment strategy.

To calculate these (entry-point) reenlistment chances across rating groups for the CY 1973 cohort merely involves multiplying a particular recruit type's average first-term survival chances (table 2) by his reenlistment rate conditional on surviving the first-term (table 5). Table 9 illustrates the results for the intercept-type recruit. By themselves, however, even the rates in this table are of limited value.

To begin profitably employing these (table 9) estimates, comparable rates for all other types of recruits also need to be calculated and then used as input to a procedure for identifying the particular rating assignment structure which would maximize the total expected number of reenlistees across all the recruits being assigned.

Maximizing the total number of reenlistees per se is not the only, nor necessarily the most sensible, goal. First-term billeting requirements, the relative importance of first-term survival compared to reenlistment, as well as other types of constraints and weights alluded to in the first section all need consideration in formalizing such an assignment strategy.

Preliminary investigation shows that the services currently employ potentially adaptable software for this problem (such as COMPASS), but several alternatives also have been examined, including both a network-type routine and a sensitivity analysis of linear programming iterations.

TABLE 9

APPENDIX A
THE 1973 COHORT

APPENDIX A

THE 1973 COHORT

The data used to estimate first-term retention probability is a longitudinal history of the Calendar Year 1973 cohort. Figure A-1 outlines the data base construction process. For each non-prior service, male recruit entering the regular Navy in CY 1973, background information and recruit training center (RTC) data is extracted from the SCAT data tape created by AFEES. This is then merged with extracts of the June and December Enlisted Master Records (EMRs) for 1973 through 1977. Loss data is incorporated from MARDAC and BuPers loss tapes and schooling data is added from the NPRDC (Naval Personnel Research and Development Center) tapes. Finally, information from the Navy change tape for the first 4 months of 1978 is added to insure identification of non-broken service reenlistments. The resulting data base is a complete longitudinal history of the first four years of service for the CY 1973 cohort.

For each rating or occupational group of interest, an extract of the longitudinal file is made which contains pre-service and early in-service characteristics, rating assignment, and variables describing the first regular tour of duty. (See reference 1 for a listing of the extraction program).

An observation is included in the sample if the individual has completed at least six months of service, has a four- or six-year term of obligation, and has been rated or designated in the rating of interest. Unrated men who have successfully completed a class A school which feeds the rating are also included. Three-year obligors are not included because the Navy no longer has a three-year USN enlistment program.

The first regular tour of duty is determined by scanning the record of each man starting with the onboard activity of the earliest available EMR. If the activity type indicates a training activity, the scan continues to the next EMR. This process continues until a non-training duty is obtained or the individual is lost (no more EMRs exist). The accounting category code is used to eliminate observations whose only non-training activity was not a regular tour of duty. For example, some recruits were confined due to medical or disciplinary problems and subsequently lost from the Navy without having reported to regular duty stations.

 $^{^{1}\}mathrm{This}$ appendix is taken from reference 1, with several minor changes.

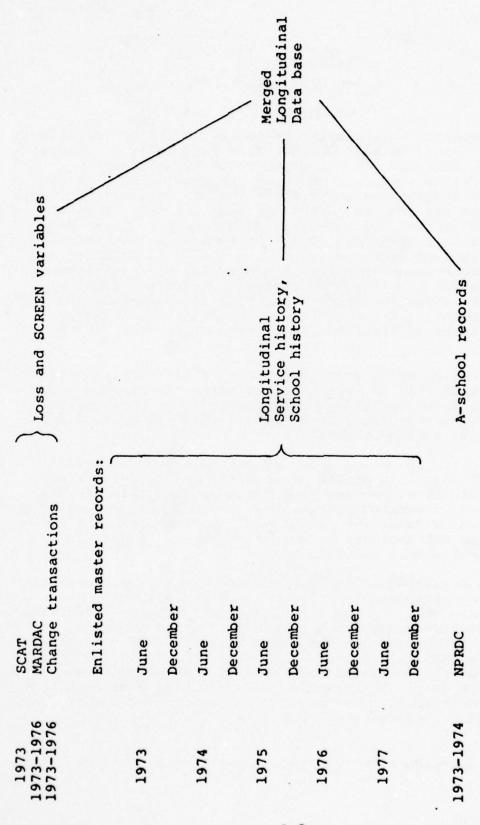

FIG.A-1: CY 1973 COHORT HISTORY FILE (1973-1977)

The activity group is determined by classifying the information in the activity type field into homogeneous groups. Table A-l shows the components of each group.

The sea, toured sea, and shore variables are created using the sea/shore code assigned to each man for rotation purposes. Table A-2 details the construction of these variables.

APPENDIX B
THE SIMPLE PROBIT MODEL

APPENDIX B

THE SIMPLE PROBIT MODEL

In estimating a recruit's chances of completing four years of service from pre-service and in-service characteristics, we would like to examine the effect of altering each characteristic while holding all others constant.

A common method for doing this specifies the variable to be estimated (survival probability) as a linear function of the other variables. Ordinary least squares (OLS) regression would then provide estimates of the survival probability and the separate effect of each independent (explanatory) variable. OLS is not strictly appropriate, however, when using a dichotomous dependent variable as we do here. (Our data indicate that a man either did or did not survive four years of service. The dependent variable can therefore take on only two values, and is dichotomous.)

Several appropriate techniques do exist for coping with dichotomous dependent variables, including the Probit model. If we let P denote the probability that a man will not complete four years of service, then the probit equation to be estimated is

Prob(loss | x) =
$$\int_{-\infty}^{B'} x/\sigma \frac{1}{\sqrt{2\pi}} \left(e^{-z^2/2} \right) dz$$
 (1)

where x is a vector of pre-service and in-service characteristics and B is the vector of coefficients of these characteristics. Estimating the B coefficients using maximum likelihood methods and evaluating the integral gives the estimated loss probability. See reference 2 for a more detailed discussion of the Probit model.

Probit model estimates of the effects of pre-service and service characteristics on four-year recruit survival probabilities need to be treated with some caution. Specifically, one cannot correctly add the probability changes (given in tables 2 and 3) associated with more than one non-intercept probability. The proper procedure involves adding the relevant probit coefficients (given in appendix D) and then converting the sum, which represents

¹This and the following paragraph are modified versions of material in reference 1.

an area under the standard normal density curve, into a probability (of four-year loss). Subtracting this estimate from 1.0 then yields the statistically correct estimate of four-year survival probability for the given recruit type of interest in a particular major rating/group.

For example, in the text of this report we roughly calculated the survival probability of a 17 year old non-Caucasian who went to boot camp at Great Lakes (RTC 1) but was otherwise the intercept type. His estimated survival chance in the health care group was shown to be approximately 63 percent. To properly calculate his survival chance, we refer to the detailed probit estimates for the health care group in appendix D (table D-12). Table D-12 indicates that the intercept coefficient is -.786, while the respective coefficients associated with being 17 years old, non-Caucasian, and from RTCl are .137, -.138, and .474. The sum of these four coefficients is -.313, which represents the "u" value in table B-1. When this sum is converted to its associated Φ in table B-1, we arrive at a four-year loss estimate of .3783. Subtracting this loss probability from 1.0 yields a four-year survival probability estimate for this type of recruit of .622 (62.2 percent), a value close but not identical to the rough estimate of 63 percent given in the text.

The reenlistment chances of CY 1973 cohort recruits who survived their first (four-year) term of service were also estimated by a Probit model. Since the reenlistment decision is a conditional one (a man must first survive the first term), the equation we estimate is

Prob(reenlisting|s,x) =
$$\int_{0}^{B'} x/\sigma \frac{1}{\sqrt{2\pi}} \left(e^{-z^2/2}\right) dz$$

where s is the conditioning fact of four-year survival.

Probit estimates of the effects of pre-service and service characteristics on reenlistment need to be interpreted carefully, as did the comparable survival estimates. The proper technique for calculating a particular survivor's reenlistment chance is identical to that for deriving a recruit's survival chance (see above), with one modification. After adding the relevant probit coefficients (given in appendix F) we merely convert the sum to a probability (of reenlistment) using table B-1. We do not then need to subtract this probability from 1.0, as we did in calculating survival rates. This is merely a mechanical difference due to the way survival was estimated compared to reenlistment, but still needs to be understood when using the probit coefficients in appendix F.

Abridged from Table II of Statistical Tables and Formulas by A. Hald, John Wiley & Sons, New York, 1952.

APPENDIX C

DISTRIBUTION OF CHARACTERISTICS OF RECRUITS IN 14 MAJOR RATINGS/GROUPS

(1973 cohort)

APPENDIX C

DISTRIBUTION OF CHARACTERISTICS OF RECRUITS IN 14 MAJOR RATINGS/GROUPS

(1973 cohort)

This appendix contains data on the percentages of 1973 recruits (in a given rating/group) with particular pre-service and service history characteristics. Substantial differences do appear across ratings/groups. For example, note that three quarters of all recruits in the sensor system groups were in MG2, while only a quarter of those in the Logistics group were so classified. Differences of that magnitude clearly reflect distinctions which the Navy believes it is important to maintain in assigning recruits to one rating or another. But the fundamental premise of this report is that some differences (and/or similarities) among rating/group recruit profiles may not be optimal for maximizing the overall survival rate. The precise assignments (depending on pre-service and early in-service characteristics) that would optimize survival will depend on the results of a formal assignment procedure.

DETAILED PROBIT ESTIMATES OF FOUR-YEAR SURVIVAL RATES IN 14 MAJOR RATINGS/GROUPS

(1973 cohort)

APPENDIX D

DETAILED PROBIT ESTIMATES OF FOUR-YEAR SURVIVAL RATES IN 14 MAJOR RATINGS/GROUPS

(1973 cohort)

NOTE: The intercept probability in each of these tables indicates the four-year average survival chance of a recruit with an "intercept-type" profile. The survival probability changes for each other characteristic show the effects of substituting that characteristic in the intercept, others held constant. A t-value greater than 1.64 indicates an effect significant at least at the .10 level.
